DATE:

DEDICATION

This dissertation is dedicated to my beloved parents and siblings, and NRE Class of 2017 whose unyielding love, support and encouragement have enriched my soul and inspired me to pursue and complete this research.

I would also like to dedicate this report to my dearly loved Daughter Tukahirwa Samantha, relatives and friends who offered me a lift all through this research in terms of advices, finances, and material support.

ACKNOWLEDGEMENT

I thank the almighty God for the gift of life and the great wisdom he has provided to me and seeing me through this case study period as well as through my entire education.

Sincere thanks also go to my beloved parents Mr. Nzairwenabo Sylvester, Ms. Tukahirwa Theresa and all my siblings for their care and love.

Special thanks also go to my academic supervisor Professor. Isabirye Moses for his constant guidance, encouragement and council throughout the dissertation period.

Lastly, I would like to thank Mrs. Manana, my friends Obong Anthony, Tugabirwe Sumaiya, Sserugo William, Barongo Collin, Mokili Sadam, Oteka Ronald, Namakula Gloria, Murungi Moreen, Daisy Andinda, Nuwampaire Julian, Owomugisha Hellen, Munyambabazi John, Nanyanzi Aisha, Derrick, Kevin Amito, Oguta Job and Nalumansi Mariam whose assistance during data collection for this dissertation was so valuable.

I furthermore want to acknowledge a debt to Mr. Kisu Kisira Henry for guiding the Natural Resource Economics class of 2017/18 academic year.

I cannot mention everyone who has immensely contributed to my studies but to you all, thanks a lot for your contribution towards this dissertation.

May the Almighty God, the Heavenly Father reward you abundantly.

ABSTRACT

This study on assessment of aboveground carbon stock in different land cover types of agriculture and forestry was carried out in Namasagali Sub County. Forests sequester and store more carbon than any other terrestrial ecosystem and are an important natural 'brake' on climate change. When forests are cleared or degraded, their stored carbon is released into the atmosphere as carbon dioxide (CO₂). According to the Kyoto Protocol, land use, land-use change, and forestry (LULUCF) are recognized as serving the role of carbon source and sink in relation to a change in land cover and carbon stocks. It also influences the amount of biomass and carbon stored in vegetation (Ipcc et al., 2019). The main objective of the study was to estimate the above ground carbon stocks in different land cover types. This was achieved by, assessing the biomass in a plot of 50 m*50 m established in all forests and all the tree stands within the chosen plots while measuring tree diameter for all qualified trees in the sampled plots with consideration of the DBH while in agriculture land cover, maize stalks were collected and weighed. The biomass was converted to carbon using the form factor "carbon = 50% of the biomass in trees and 0.45[^] (19). In this study, it was found out that carbon stock was highest in forest land cover especially under eucalyptus plantation and least in agriculture, maize in particular. It was also confirmed through hypothesis testing there is significant variation in carbon stock capacity among different land cover types, where the overall Prob > chi² = 0.0007. The study concludes that there was a variation in carbon pools in different land-cover types in Namasagali, where ABGC stock estimated was highest in forestry ranging from eucalyptus plantation to agro-forestry land-cover and least in agriculture, maize in particular. However, it was realized in the study that the dry mass of maize stored very low carbon content because much of the carbon was accumulated in soil to form soil organic carbon (SOC) during maturity of maize. However, it emphasized that planting of more fast growing tree species such as eucalyptus to increase on the terrestrial carbon sink capacity and need for establishment of schemes such as payment of ecosystem services (PES), carbon markets such that the individuals practicing conservation are rewarded.

Keywords: Carbon stock, Land cover, Aboveground, Biomass

CHAPTER ONE: INTRODUCTION

1.1 Background of the study

Forests sequester and store more carbon than any other terrestrial ecosystem and are an important natural 'brake' on climate change. When forests are cleared or degraded, their stored carbon is released into the atmosphere as carbon dioxide (CO₂). According to the Kyoto Protocol, land use, land-use change, and forestry (LULUCF) are recognized as serving the role of carbon source and sink in relation to a change in land cover and carbon stocks. It also influences the amount of biomass and carbon stored in vegetation (Ipcc et al., 2019). Tropical deforestation is estimated to have released of the order of 1–2 billion tonnes of carbon per year during the 1990s, roughly 15–25% of annual global greenhouse gases (GHGs) emissions (Fearnside and Laurance 2003; Houghton 2005). The largest source of GHGs emissions in most tropical countries is from deforestation and forest degradation. So, that terrestrial ecosystem in the global carbon cycle has raised considerable interest among researchers and policy makers. Exchange between atmosphere and vegetation involves large two way fluxes, with fixation of CO₂ into biomass through photosynthesis approximately balanced by the release of CO₂ through processes of decomposition and burning. It is estimated about 60 Pg carbon is exchanged (in both directions) between terrestrial ecosystems and the atmosphere every year, with a net terrestrial uptake of 0.7±1.0 Pg C (Lasco 2002).

However, relative to the size of the atmospheric pool of CO₂, land use change and forest conversion are significant source of CO₂ contributing to around 1.7±0.6 Pg C per year. Current efforts to mitigate the impact of climate change are through ways of increasing carbon sequestration and/or mitigating carbon emission (Roxburgh et al. 2006). Increased carbon stocks (carbon sequestration) can be achieved by (1) natural increases in forest growth and biomass, (2) increasing tree stocks in existing forest either through increasing growth or decreasing harvest and (3) establishing fast growing tree plantation (Niles 2002). Carbon sequestered is stored in the form of woody biomass, thus the simple way to increase carbon stock is to plant and manage trees (Bonino 2006). Terrestrial carbon stocks consist of above and below ground carbon. Above ground carbon stocks component includes biomass (stems, twigs, leaves, vines, epiphytes and
